

I built a random forest classifier and found that `account_age_days` (a feature I engineered that represents the age of the account in days) was by far the most important and strongest predictor of user adoption, contributing over 90% of the model's predictive power. This makes sense because users who joined earlier have had more time to establish the required login patterns.

Model Accuracy: 0.8642				
Classification Report Summary Table:				
	precision	recall	f1-score	support
False	0.867	0.997	0.927	2080.000
True	0.125	0.003	0.006	320.000
accuracy	0.864	0.864	0.864	0.864
macro avg	0.496	0.500	0.467	2400.000
weighted avg	0.768	0.864	0.804	2400.000

While the model has high overall accuracy (86%), its low recall for adopted users suggests that adoption is difficult to predict solely from sign-up metadata, implying that behavioral factors post-signup are likely more influential.
